Graphical Abstract:

Note: The percentage changes of (a) environmental inefficiency score, (b) GDP, and (c) emission intensity of seven Chinese regions when changing emission charge policy from pollutant discharge fees to environmental taxes.

Abstract: Emission charge policy has recently switched from pollutant discharge fees to environmental taxes in China. Considering spatial heterogeneity, the effects of changes in emission charge policy may subject to different Chinese regions. In this study, environmental efficiencies of Chinese regions are evaluated through provincial environmentally extended input-output tables and a frontier-based optimization model. Driving factors of environmental productivity growth are identified through global Luenberger productivity decomposition approach. Moreover, spatial heterogeneity on the effects of change in emission charge policy on environment and economy are assessed. Results show that all regions experienced environmental productivity growth. Technology progress is the major driving factor in most regions with an average contribution of 90%, while technical efficiency regress slows environmental productivity growth in Southwest region. Switching from pollutant discharge fees to environmental taxes would decrease emission intensities by 1.42% on average, but it would have different negative impact on economic growth (-1.13%~ -4.90% of regional GDP) due to spatially heterogeneous trade-offs between environmental protection and economic development. Addressing such spatial heterogeneity provide not only a basis for diversified tax rate determination but also a framework for other environmental policy assessment.

Highlights

- ◆ Environmentally extended input-output tables for Chinese provinces are proposed.
- ◆ Input-output analysis is combined with frontier-based optimization model.
- ◆ Environmental productivity growth and its driving factors are identified.
- ◆ Effects of replacing pollutant discharge fees with environmental taxes are assessed.
- ◆ Spatial heterogeneity on effects of emission charge policy change is considered.

1. Introduction

Industrialization and urbanization caused by rapid economic development lead to over-energy consumption in China. Currently, China is the biggest country of energy consumption in the world, ranking the top of the growth in global energy consumption for 17 years (BP, 2018). In 2017, China accounted for 23.2% and 33.6% in the global energy consumption and the growth in global energy consumption, respectively (BP, 2018). Due to the excessive energy consumption, environmental pollutions are becoming increasingly serious in China, especially air pollutions and water pollutions. During the 12th Five-Year period, China dominated approximately 30% of global sulfur dioxide (SO₂) emission and 20% of global nitrogen oxides (NO_x) emission per annum (Zhang et al., 2018). Meanwhile, particulates emissions, including soot and dust (SD) (Liang et al., 2016) and particulate matter (Song et al., 2017) are also at high levels in China. Because of the severe air pollutions, the number of heavy pollution days raise continually and about one third of Chinese cities struggle with fog and haze issues (Xie et al., 2018). Beside air pollutions, series of water pollutions intensify the problem of scarcity of drinking water supply. For instance, the Yangtze River, which is the source of drinking water for up to 800 million (M) people, undertakes the most proportion of national water polluted industrial activities (Chen et al.,

2018b). As a result of water pollution, there are about 190M people fall sick and 60 thousand people die each year in China (Tao & Xin, 2014). Moreover, heavy metal pollutions like Hg, Cd, Pb, As, Cu, and Zn are other factors of public health risk (Li et al., 2014).

Facing severe environmental and ecological problems and their effects on public health, Chinese government has enacted laws and implemented policies to handle environmental problems since the last century (Feng & Liao, 2016). For example, in order to control emissions, Air Pollution Prevention and Control Action Plan has been issued in 2013 and Environmental Protection Law has been implemented in 2015 in China, which have pressured local authorities to increase penalties for environmental violations. Additionally, Chinese government has set explicit emission reduction targets for major pollutions since the 11th Five-Year Plan (Yang et al., 2018). And ecological protection targets are completed in the 13th Five-Year Plan for Eco-environmental Protection. Those policies did have positive effects on slowing down the rate of emission growth to some extent. In 2017, carbon emission increased 1.6% in China, which was the half of the average rate over the past decade (BP, 2018). Other pollutions met the corresponding emission targets as well (Wang et al., 2014). However, environmental policies associated with emission abatement and environmental protection will limit production and further reduce economic growth, in other words, there are trade-offs between environmental protection and economic development. It has been confirmed that strict environmental policies would have a negative impact on GDP in China (Ahmed & Ahmed, 2018).

Therefore, both economic and environmental perspectives need to be contained in order to have a more comprehensive estimation of policy effects. Environmental efficiency is one of the solutions to measure policy effects on economy and environment. In this study, environmental efficiency is defined as the improved potential to achieve more industrial outputs with less resource inputs as well as more emission abatement. Methods of efficiency estimation can be roughly divided into statistical approaches (Semenyutina et al., 2014), parametric analysis, e.g. linear programming (Du & Mao, 2015), parametric meta-frontier analysis (Du et al., 2016), and parametric hyperbolic distance function approach (Duman & Kasman, 2018), and non-parametric analysis. Data envelopment analysis (DEA) is a widely used non-parametric approach to measure sector-varying (Bi et al., 2014), region-varying (Chen & Jia, 2017), or time-varying (Wang et al.,

1 83 2013) environmental efficiency. Furthermore, DEA can also be improved by combining life cycle
2 84 assessment (Lorenzo-Toja et al., 2018), input-output analysis (IOA) (Xing et al., 2018), and index
3
4 85 or statistical analysis (e.g. Malmquist index used in Woo et al. (2015); bootstrapping approach
5
6 86 applied in Yang & Zhang (2018)). However, studies mentioned above have certain limitations.
7
8 87 First, the results were probably biased because environmental efficiencies were measured under
9
10 88 the independent constraints of economy and environment. Second, the sensitivity to environmental
11
12 89 policy depends on different industrial sectors, high energy intensity sectors and high emission
13
14 90 sectors tend to be strongly influenced by environmental policies. But the difference among
15
16 91 industrial sectors and the material flow existed in industrial sectors are neglect. Third, there is
17
18 92 obvious heterogeneity among different regions in China, environmental efficiency measured at
19
20 93 national level cannot figure out the regional diversity.

21
22
23 94 In this study, in order to measure environmental efficiency in view of the inter-sector
24
25 95 heterogeneity and material flow existed in industrial sectors, we combine IOA and DEA and
26
27 96 propose a frontier-based optimization model with uniform formulations of both economic and
28
29 97 environmental constraints. For purpose of evaluating effects of emission charge policies on
30
31 98 environment and economy, we estimate environmental efficiencies in seven geographical regions
32
33 99 in China (the region category is attached in Table S1) using this optimization model. First, we
34
35 100 calculate the environmental inefficiency scores of seven Chinese regions through the conventional
36
37 101 model and the improved optimization model. Then, in order to evaluate the environmental
38
39 102 productivity change of each region, we decompose the driving factors of environmental
40
41 103 inefficiency score measured by DEA into technical efficiency change (EC) and best practice gap
42
43 104 change (BPC) by using global Luenberger productivity indicator (GLPI). Finally, we compare the
44
45 105 changes of environmental efficiency, GDP and the emission intensity under different emission
46
47 106 charge policies and evaluate the synergistic effects of pollutant emission and carbon emission
48
49 107 reduction.

50
51
52
53 108 This study contributes to the existing research at the theoretical and the application level in
54
55 109 the following aspects. First, taking spatial heterogeneity and the trade-offs between economic
56
57 110 development and environmental protection into consideration, the effects of switching pollutant
58
59 111 discharge fees for environmental taxes are assessed. Second, the compiled environmentally

112 extended input-output tables for 30 Chinese provinces distinguish abatement costs and
113 environmental benefits from monetarily valued material flows among various industrial sectors.
114 Third, the frontier-based optimization model provides a framework of environmental efficiency
115 measurement which has the uniform and connective constraints of economy and environment.
116 Based on this model, an environmental efficient benchmark could be obtained, so that different
117 policy scenarios could be compared without the impacts of efficiency change. Fourth,
118 environmental productivity growth and its driving factors are identified based on Luenberger
119 productivity indicator.

120

121 **2. Methods and data**

122 **2.1. Environmentally extended input-output analysis for efficiency measurement**

123 Environmentally extended input-output analysis (EEIOA) is widely applied to assess the
124 environmental impacts related to energy consumption (Chen et al., 2018a), pollutant emission, e.g.
125 CO₂ (Meng et al., 2018) and mercury emissions (Li et al., 2015), efficiency measurement
126 (Aguilar-Hernandez et al., 2018), and improved potential evaluation at regional level (Mi et al.,
127 2015) or national level (Mi et al., 2017). The advantage of EEIOA is that the relationship between
128 environment and economy is treated in one unitary and closed monetarily valued material flow.
129 Besides, each sector's characteristics can be captured through multi-sector input-output table. In
130 addition, impacts of environmental policies include both the effects of policy itself and the effects
131 of efficiency changes associated with policy reform. Thus, in order to evaluate the effects of
132 environmental policy itself on environment and economy, the impacts of efficiency change
133 required to be eliminated, so that different policy scenarios could be compared under the same
134 environmental efficient benchmark. Therefore, frontier-based optimization model is developed by
135 combining EEIOA and DEA to calculate environmental inefficiency score. The framework is
136 illustrated as in Figure 1.

| Aims | Methods | Policies | Years |
|--|---|--|-------------------|
| Environmental efficiency calibration | Conventional model + Frontier-based optimization model | Environmental taxes | 2012 |
| Environmental productivity decomposition | Frontier-based optimization model + Luenberger productivity indicator | Environmental taxes | 2012 + 2007 |
| Environmental policy simulation | Frontier-based optimization model | Environmental taxes + Pollutant discharge fees | 2012 |

Figure 1. The research framework. Conventional model and Frontier-based optimization model is represented as model (1) and model (2), respectively.

Taking the reference of [Mahlberg & Luptacik \(2014\)](#), the conventional model (model (1)) is proposed with the separate emission constraint and economic constraint based on the conventional input-output table. δ is environmental inefficiency score, indicating the improved potential away from the frontier of the specific year to be analyzed. x is the $n \times 1$ total output vector, while e is the $m \times 1$ total produced pollution vector. A is the $n \times n$ intermediate use coefficient matrix, indicating the intermediate use per unit of total output of each industrial sector. EI is the $m \times n$ emission intensity matrix, showing the emission per unit of total output of each industrial sector. While B is the $k \times n$ primary input coefficient matrix, representing the primary input per unit of total output of each industrial sector. n , m , and k stand for the number of industrial sector, the kind of emission, and the number of primary input, respectively. In this study, n , m , and k equals to 42, 16, and 4, respectively. Notations with superscript 0 are parameters. IM^0 , IF^0 , ERR^0 , and TFU^0 come from the conventional input-output table, meaning imports vector, inflow vector, error vector and total final use vector of industrial sector, respectively. AT^0 is the $m \times 1$ emission abatement target, while

153 z^0 is the $k \times 1$ social available vector. This model aims at optimizing the environmental inefficiency
 154 score. The first constraint means that for each industrial sector, the optimal total output minus
 155 intermediate use should not be less than the observed total final use. The second constraint means
 156 that for each pollutant, the optimal produced pollution minus emission load should not be less than
 157 the observed abatement target. While the third constraint means that for each primary input, the
 158 optimal primary input should not be higher than the observed social available resource. In this
 159 model, all economic variables and parameters are valued in monetary unit Yuan, while all
 160 environmental variables and parameters are valued in physical unit kg-equivalent.

$$\begin{aligned}
 & \max_{x, e, \delta} \delta \\
 & s.t. \\
 161 \quad & x - A \cdot x + IM^0 + IF^0 - ERR^0 \geq (1 + \delta)TFU^0 \quad (1) \\
 & e - EI \cdot x \geq (1 + \delta)AT^0 \\
 & B \cdot x \leq (1 - \delta)z^0 \\
 & x, e, \delta \geq 0
 \end{aligned}$$

162 As mentioned before, the conventional input-output table cannot figure out emission
 163 abatement cost and abatement benefit. Besides, inputs for productive activities and inputs for
 164 abatement activities cannot be identified as well. That is to say, the environmental value is
 165 aggregated with productive value in the conventional input-output table.

166 In order to distinguish inputs for emission abatement and quantify environmental value, we
 167 establish environmentally extended input-output tables (Wang et al., 2018) for each Chinese
 168 province in 2007 and 2012 by introducing sixteen emission abatement sectors (see Table S2).
 169 Intermediate inputs from industrial sectors to emission abatement sectors are served by emission
 170 abatement costs, while intermediate inputs from emission abatement sectors to industrial sectors
 171 are presented by emission charges, which can be understood as emission rights. Regarding final
 172 outputs of emission abatement sectors, environmental benefits associated with emission abatement
 173 denote the total final use of emission abatement sectors. Additionally, total outputs and primary
 174 inputs of emission abatement sectors are calculated through the balance of Leontief input-output
 175 matrix. Thus, monetary values of environment and economy can be provided through an
 176 integrated and balanced input-output matrix.

177 Based on these environmentally extended input-output tables, an improved environmental
 178 efficiency measured model is proposed as model (2). Compared with the conventional model, the
 179 improved one has two significant superiorities. First, it is capable of capturing the interrelated
 180 relationship between environment and economy under one integrated framework. Any changes in
 181 emission control and emission discharge affected by environmental policy will have an effect on
 182 material flow among industrial sectors, and this effect can be measured in the extended
 183 input-output table and the improved model. Second, the improved model distinguishes inputs for
 184 emission abatement and separates environmental values (such as emission abatement cost and
 185 emission charge) from productive values. Moreover, all variables and parameters in model (2) are
 186 valued in monetary unit Yuan.

$$\begin{aligned}
 & \max_{x_{1,t}, x_{2,t}, \delta_t} \delta_t \\
 & s.t. \\
 & x_{1,t} - A_{11,t} \cdot x_{1,t} - A_{12,t} \cdot x_{2,t} + IM_t^0 + IF_t^0 - ERR_t^0 \geq (1 + \delta_t) TFU_{1,t}^0 \\
 & x_{2,t} - A_{21,t} \cdot x_{1,t} - A_{22,t} \cdot x_{2,t} \geq (1 + \delta_t) TFU_{2,t}^0 \\
 & B_{1,t} \cdot x_{1,t} + B_{2,t} \cdot x_{2,t} \leq (1 - \delta_t) z_t^0 \\
 & x_{1,t}, x_{2,t}, \delta_t \geq 0
 \end{aligned} \tag{2}$$

188 Here, all notations are derived from the environmentally extended input-output table. The
 189 subscript t is a symbol of the accounting periods, which will be detailed explained in Section 2.2.
 190 δ_t , IM_t^0 , IF_t^0 , ERR_t^0 , z_t^0 have the same meanings as in model (1). x_1 and x_2 serves as $n \times 1$
 191 total output vector of industrial sector and $m \times 1$ total output vector of emission abatement sector
 192 (environmental value), respectively. Similarly, TFU_1 and TFU_2 represents total final use of
 193 industrial sector and total final use of emission abatement sector (environmental benefit associated
 194 with emission abatement), respectively. B_1 and B_2 show primary input coefficient matrixes of
 195 industrial sector ($k \times n$) and emission abatement sector ($k \times m$). A_{11} is the $n \times n$ intermediate input
 196 coefficient matrix from industrial sector to industrial sector, which has the same meaning but
 197 different value with A in model (1) because of the environmental extension. A_{12} is the $n \times m$
 198 intermediate input coefficient matrix from industrial sector to emission abatement sector,
 199 representing emission abatement cost per unit of environmental value. A_{21} is the $m \times n$ intermediate

200 input coefficient matrix from emission abatement sector to industrial sector, denoting emission
 201 charge per unit of total industrial output. A_{22} is the $m \times m$ intermediate input coefficient matrix
 202 from emission abatement sector to emission abatement sector, which is a zero valued matrix
 203 because environmental taxes are levied at economic sectors and abatement costs (or environmental
 204 taxes) related to secondary emission during abatement process are included in economic sectors.
 205 The formulation of model (2) is similar with model (1), except the second constraint. Since all
 206 environmental concepts are quantified monetarily in the improved input-output table, the second
 207 constraint gives the lower bound of abatement benefit instead of the physical valued emission
 208 abatement target of each emission abatement sector, denoting the optimal environmental value
 209 minus emission charge should not be less than the observed abatement benefit.

210

211 2.2. Luenberger productivity indicator for driving factors decomposition

212 Changes of environmental inefficiency score between different years indicates the
 213 improvement or deterioration of environmental productivity. One of the aims of this study is to
 214 evaluate the environmental productivity change of each region over two separate years, which are
 215 2007 and 2012. For this purpose, taking the reference of Wang et al. (2016), we define the global
 216 Luenberger productivity indicator (GLPI) over the two years to measure the change of
 217 environmental productivity. GLPI is superior to the traditional Luenberger productivity indicator
 218 in solving several problems such as failing circularity, spurious technical regress and infeasible
 219 situation (Wang & Wei, 2016). Equation is shown as follows:

$$220 \quad GLPI(x_{1,t}, x_{2,t}; x_{1,t+1}, x_{2,t+1}) = \delta_t^G(x_{1,t}, x_{2,t}) - \delta_{t+1}^G(x_{1,t+1}, x_{2,t+1}) \quad (3)$$

221 The progress of environmental productivity could be explained as the reduction of
 222 environmental inefficiency score. Thus, the difference of global environmental inefficiency scores
 223 between the two years is used to measure the environmental productivity change. The positive,
 224 negative, and zero values mean improvement, deterioration, and invariability of environmental
 225 productivity, respectively. δ^G is the global environmental inefficiency score and can be
 226 calculated by model (4), indicating the improved potential away from the frontier of the panel data

227 set for a period. $\delta_t^G(x_{1,t}, x_{2,t})$ and $\delta_{t+1}^G(x_{1,t+1}, x_{2,t+1})$ are distinguished by the two separate
 228 periods t and $t+1$. In this study, t and $t+1$ represent 2007 and 2012, respectively.

$$\begin{aligned}
 & \max_{x_{1,t}, x_{2,t}, \delta_t^G} \delta_t^G \\
 & s.t. \\
 229 \quad & x_{1,t} - A_{11,t} \cdot x_{1,t} - A_{12,t} \cdot x_{2,t} + IM_t^0 + IF_t^0 - ERR_t^0 \geq (1 + \delta_t) TFU_{1,t}^0 \quad (4) \\
 & x_{2,t} - A_{21,t} \cdot x_{1,t} - A_{22,t} \cdot x_{2,t} \geq (1 + \delta_t) TFU_{2,t}^0 \\
 & B_{1,t} \cdot x_{1,t} + B_{2,t} \cdot x_{2,t} \leq (1 - \delta_t) z_T^0 \\
 & x_{1,t}, x_{2,t}, \delta_t^G \geq 0
 \end{aligned}$$

230 Model (4) is the optimization model for global environmental inefficiency score. The
 231 subscript t is a symbol of the exact year to be analyzed. All constrains are same as those in model
 232 (2) except the definition of z_T^0 . In model (2), z^0 is the social available vector of a specific year.
 233 While in model (4), z_T^0 is the maximum value of social available vector during a period
 234 (between t and $t+1$ in this study), providing the global input frontier. Solving model (4) twice for
 235 year t and $t+1$, the two years' global environmental inefficiency scores can be obtained.

236 Furthermore, in order to figure out the main driving factors of the environmental productivity
 237 change in each region, GLPI is decomposed into efficiency change (EC) and best practice gap
 238 change (BPC), which are illustrated in Eqs. (5) and (6). EC is the difference of the two separate
 239 periods of environmental inefficiency scores (δ_t). While BPC is the difference of the two separate
 240 periods of the distance between global environmental inefficiency scores (δ_t^G) and environmental
 241 inefficiency scores (δ_t).

$$242 \quad EC = \delta_t(x_{1,t}, x_{2,t}) - \delta_{t+1}(x_{1,t+1}, x_{2,t+1}) \quad (5)$$

$$243 \quad BPC = [\delta_t^G(x_{1,t}, x_{2,t}) - \delta_t(x_{1,t}, x_{2,t})] - [\delta_{t+1}^G(x_{1,t+1}, x_{2,t+1}) - \delta_{t+1}(x_{1,t+1}, x_{2,t+1})] \quad (6)$$

244 EC is the average gain or loss related to the technical efficiency change from period t to
 245 period $t+1$, capturing the movement with the same or opposite direction of the technology frontier.
 246 BPC is the average gain or loss due to the technology change from period t to period $t+1$,

1 247 indicating the best practice gap change between the global technology frontier and each period's
2 248 technology frontier (Wang et al., 2016). The positive (or negative) values of EC and BPC
3
4 249 represent technical efficiency increase (or decrease) and technology progress (or regress),
5
6 250 respectively.

17 254 Economic Accounting, National Bureau of Statistics of China. The last two issues of provincial
18
19 255 input-output tables with 42 industrial sectors of 30 Chinese provinces in 2007 and 2012 are used
20
21 256 as the basic economic datasets. The sector category is in line with that in 2012 input-output tables
22
23 257 (see Table S2). Given that labour and capital are the main sources of extensible primary inputs, the
24
25 258 social available resource z^0 is calculated based on the weighted average of the extensible rates of
26
27 259 labour and capital with the weight equaling to the proportion of each primary input to the total
28
29 260 primary input. The extensible rates for the whole country and 30 regions are measured based on
30
31 261 unemployed population and depreciation of original value of fixed assets, approximately ranging
32
33 262 from 10% to 50%. For easier discussion, we assume the same extensible rate in all primary inputs
34
35 263 and all provinces, thus we take 30% as the extensible rate of primary input and 130% as the social
36
37 264 available resource z^0 .

38
39
40 265 As for environmental data, we get the national emission loads of the sixteen pollutants in
41
42 266 2007 and 2012 from Chinese Environmentally Extended Input- Output (CEEIO) Database (Liang
43
44 267 et al., 2017). Values of national emission abatement cost come from Department of Industry
45
46 268 Statistics of National Bureau of Statistics of China and are distributed to each pollutant by their
47
48 269 emission proportion. We allot the national emission loads and national emission abatement cost to
49
50 270 provincial ones by the provincial energy consumption proportion. Total final use of emission
51
52 271 abatement sector (environmental benefit associated with emission abatement) is measured by the
53
54 272 product of emission abatement load and the health costs per unit of emission. According to World
55
56 273 Bank (2007), total health costs of air pollution and water pollution in China is 3.8% of GDP and
57
58 274 2.0% of GDP, respectively.
59

275

276 2.4. Pollutant equivalents transformation

277 Given that each pollutant has different environmental effects, same emission loads of
278 different pollutants will pose different degrees of negative impacts on environment. Thus, it is
279 necessary to unify the negative effects of various pollutants on environment and public health.
280 China's Ministry of Environmental Protection published a list of taxable pollutants and the
281 corresponding "pollutant equivalent", which could be applied to transfer the physical units (E_{phy})
282 of emission loads of different pollutants to the equivalent units (E_{equ}) according to their
283 environmental and health impacts (Zhang et al. 2018). The equivalent units (k) are listed in Table
284 S3, serving as the coefficients to divide emission loads in physical units (E_{phy}): $E_{equ}=E_{phy}/k$.

285

286 3. Results

287 3.1. Environmental efficiency calibration

288 Figure 2 shows the bias degrees of improved potential at regional level. Improved potential
289 implies the distance between optimized value and observed value. The conventional model tends
290 to underestimate environmental inefficiency score, economic indicators (GDP and total output),
291 and environmental indicators (emission and emission intensity). The bias degree of environmental
292 inefficiency score is not obvious. Specifically, the biased degree of environmental inefficiency
293 score in South coast region rank the top, valued -21%. While the biased degree of emission
294 intensity is large, which is -48% in Northeast region, -4% in North region, 362% in East coast
295 region, -85% in South coast region, -64% in Central region, -35% in Northwest region, and -333%
296 in Southwest region, respectively. It can be explained that values of emission intensity are too tiny,
297 any small changes would result in large bias degrees. From the spatial heterogeneity perspective,
298 the conventional model is inclined to underestimate indicators of most regions, but overestimate
299 indicators of economically developed region. Specifically, bias degree in East coast region of
300 environmental inefficiency score, GDP, total output, emission, and emission intensity is 3%, 14%,
301 41%, 86%, and 362%, respectively. Besides, the bias degrees of five indicators in North region is

the lowest. Over all, the improved model corrects the overestimated economic and environmental indicators in East coast region, and corrects the underestimated economic and environmental indicators in other regions.

Figure 2. The bias degree of improved potential of model (1) over model (2) in seven Chinese regions. Five indicators are considered, which are environmental inefficiency, GDP, total output, emission, and emission intensity. Improved potential dominates the difference between optimal value and observed value. Values in this figure are measured through dividing the difference between the improved potentials of model (1) and model (2) by the improved potential of model (2), representing the bias degree of improved potential of model (1) compared with model (2). The positive (or negative) value means that model (1) overestimates (or underestimates) the corresponding indicator.

3.2. Environmental productivity decomposition

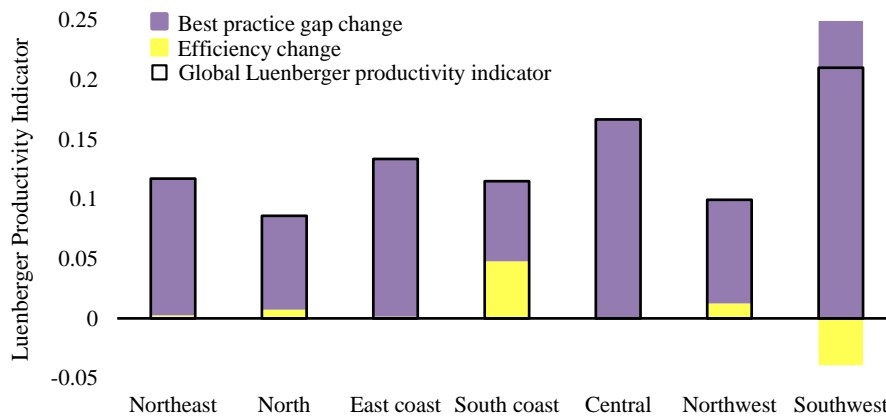

Figure 3 displays the environmental productivity change and the corresponding driving factors of each region. North region and Northwest region are the bottom two regions in environmental productivity progress, valued 0.0860 and 0.0994 in GLPI, respectively (see Table 1). It is because that industrial-oriented economic structures in these regions pose negative effects

321 on environment and further on environmental efficiency. For instance, North region has intensive
 322 high energy consumption and high emission enterprises, such as thermal power plants, coking
 323 factories and large installed electricity generation facilities (Liu et al., 2018). Specially, the large
 324 vehicle population in Beijing and the high level of agricultural and animal activities in Hebei and
 325 Henan provinces aggravate emission degree in North region (Liu et al., 2018). Besides, the
 326 developed mining and oil processing industries produce serious environmental pollution due to the
 327 rich mineral resources in Northeast region.

328
 329 **Table 1** Environmental inefficiency score and the driving factors decomposition. Environmental
 330 inefficiency scores of the two specific periods are calculated by model (2). Environmental
 331 productivity changes from 2007 to 2012 are represented by GLPI, which is measured by model (4).
 332 Two driving factors BPC and EC are decomposed from GLPI by Eqs. (5) and (6).

| Region | Environmental inefficiency score | | BPC | EC | GLPI | Percentage contribution (%) | |
|-------------|----------------------------------|--------|--------|---------|--------|-----------------------------|--------|
| | 2007 | 2012 | | | | BPC | EC |
| | Northeast | 0.0924 | | | | 0.0897 | 0.1147 |
| North | 0.0850 | 0.0783 | 0.0787 | 0.0073 | 0.0860 | 91.51 | 8.49 |
| East coast | 0.0691 | 0.0691 | 0.1320 | 0.0016 | 0.1336 | 98.83 | 1.17 |
| South coast | 0.0870 | 0.0393 | 0.0672 | 0.0478 | 0.1149 | 58.45 | 41.55 |
| Central | 0.0962 | 0.0968 | 0.1673 | -0.0004 | 0.1668 | 100.26 | -0.26 |
| Northwest | 0.0854 | 0.0722 | 0.0868 | 0.0126 | 0.0994 | 87.34 | 12.66 |
| Southwest | 0.0559 | 0.0957 | 0.2493 | -0.0392 | 0.2101 | 118.64 | -18.64 |

333

334

335 **Figure 3.** Environmental productivity indicators of seven Chinese regions. The bars outlined in
 336 black show GLPIs. The purple colored bars and yellow colored bars represent BPCs and ECs,

1 337 respectively. GLPI is the sum of EC and BPC. The positive and negative values of GLPI stand for
2 338 environmental productivity growth and reduction, respectively. The positive (or negative) values
3
4 339 of EC and BPC represent technical efficiency increase (or decrease) and technology progress (or
5
6 340 regress), respectively.
7

8
9 341

10
11 342 Furthermore, according to the positive or negative driving factors, the seven Chinese regions
12
13 343 can be divided into three modes, which are technology dominant mode (mode one), efficiency
14
15 344 impeditive mode (mode two), and co-driven mode (mode three). Most of the regions belong to
16
17 345 mode one, except South coast region and Southwest region. According to GLPI, environmental
18
19 346 productivity increases by 0.1172 in Northeast region, 0.0860 in North region, 0.1336 in East coast
20
21 347 region, 0.1668 in Central region, and 0.0994 in Northwest region, respectively. And technical
22
23 348 improvement dominates 97.87%, 91.51%, 98.83%, 100.26%, and 87.34%, respectively (see [Table](#)
24
25 349 [1](#)). Since the 1980s, in order to comply with the international development tendency and
26
27 350 reconstruct national economic development structure as well as redevelop an
28
29 351 environmental-friendly oriented economy, China has implemented the following development
30
31 352 strategies successively: Coastal Development Strategy for Eastern coast region, the Great Western
32
33 353 Development Strategy for Northeast region and Northwest region, Revitalization of the Old
34
35 354 Northeast Industrial Base Strategy for Northeast region, and Mid-China Rising strategy for
36
37 355 Central region. This series of strategies encourages local factories to renovate technology and
38
39 356 eliminate backward productive technique. Thus, the best practice gap compared with regions in
40
41 357 the frontier has been narrowed and the technology progresses a lot.
42
43
44

45 358 Southwest region belongs to mode two due to the negative EC (valued -0.0392). However,
46
47 359 GLPI of Southwest region (0.2101) is the highest over the **seven** regions, even if the technical
48
49 360 efficiency change has a passive effect on environmental productivity progress. The high level of
50
51 361 environmental productivity progress in Southwest region might be correlated with the excellent
52
53 362 resource endowment and environmental conditions. It has been pointed out that the abundant
54
55 363 energy and forest resources and well-developed clean electricity generation method of hydropower
56
57 364 lead to low carbon emission ([Tao et al., 2016](#)), and further lead to high environmental efficiency.
58
59
60

1 365 However, the industrial development actions which have negative impacts on the local
2 366 environment leads to a significant decline in technical efficiency. For example, the establishment
3
4 367 of the large petrochemical industrial base has resulted in air and water pollution in Sichuan
5
6 368 province. Moreover, pollutant emissions from local phosphorus chemical industry generates
7
8 369 chronic poisoning to nearby residents and livestock in Yunnan province.

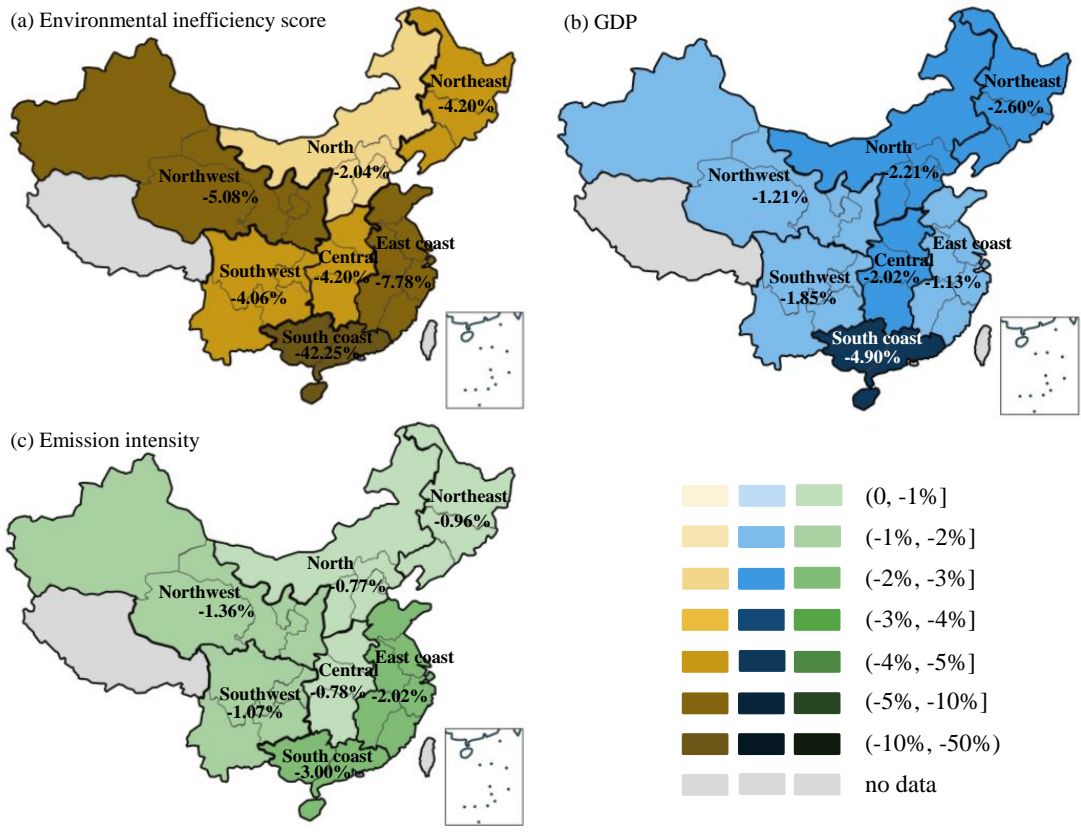

10
11 370 Mode three includes South coast region. The two driving factors have similar effects on
12
13 371 environmental productivity change in this region. More specific, BPC and EC contribute to
14
15 372 environmental productivity progress by 58.45% and 41.55%, respectively. On one hand, from the
16
17 373 national trade perspective, South coast region is the outflow place of air pollution and solid waste
18
19 374 (Wu, 2016). On the other hand, because of the superior geographical position and abundant capital,
20
21 375 South coast region can timely learn advanced emission control technology. Thus, technical
22
23 376 efficiency progress and technology improvement promote environmental productivity at the same
24
25 377 time.

26
27
28 378

29 379 **3.3. Effects evaluation of emission charge policies on economy and environment**

30
31
32
33
34 380 In this study, two emission charge policies are considered, which are pollutant discharge fees
35
36 381 and environmental taxes. From the beginning of 2018, environmental taxes policy has been
37
38 382 implemented with the enactment of “Environmental Protection Tax Law”, replacing the pollutant
39
40 383 discharge fees policy which was implemented from 2003. The environmental taxes policy
41
42 384 formulates environmental tax rate for each taxable pollution. It has been decided that the range of
43
44 385 environmental tax rates of air pollution and water pollution is from 1.2 Yuan/ kg-equivalent to 12
45
46 386 Yuan/ kg-equivalent and from 1.4 Yuan/ kg-equivalent to 14 Yuan/ kg-equivalent, respectively.
47
48 387 While the pollutant discharge fees of air pollution and water pollution is 0.6 Yuan/ kg-equivalent
49
50 388 and 0.7 Yuan/ kg-equivalent, respectively. The detailed tax rates of different pollutions in different
51
52 389 provinces are listed in [Table S4](#).

53
54
55 390

391

392 **Figure 4.** The percentage changes of (a) environmental inefficiency score, (b) GDP, and (c)
 393 emission intensity of seven Chinese regions when changing emission charge policy from pollutant
 394 discharge fees to environmental taxes. The black thick lines are the regional boundaries, while the
 395 grey thin lines are the provincial boundaries. Blocks in grey are not included in our study due to
 396 the lack of data, which are Tibet, Taiwan, Hongkong, and Macao, respectively. Darker colored
 397 block represents higher percentage change. The range of percentage change of each hierarchical
 398 color is shown as the legend.

399

400 In order to evaluate the effects of the increased tax rates of various pollutions on efficiency,
 401 economy, and environment, we calculate the percentage changes of environmental inefficiency
 402 scores, GDP, and emission intensity of seven Chinese regions when changing environmental
 403 policy from pollutant discharge fees to environmental taxes policy (shown as [Figure 4](#)).
 404 Percentage changes of environmental inefficiency score stand for the effect of environmental
 405 policy on environment, percentage changes of GDP reveal the effect of environmental policy on

406 economic development, while percentage changes of emission intensity show the complex effect
 407 on both environment and economy. It can be seen that raising emission charge, environmental
 408 inefficiency scores would have obvious declines, and emission intensity would be decreased by
 409 1.42% on average. We further calculate the median for each indicator, which is illustrated in [Table](#)
 410 [2](#). According to the relationship between absolute values and median of each indicator, these seven
 411 regions can be additionally divided into four patterns, which are high economic effect – high
 412 environmental effect (H-H) pattern, high economic effect – low environmental effect (H-L)
 413 pattern, low economic effect – high environmental effect (L-H) pattern, and low economic effect –
 414 low environmental effect (L-L) pattern.

415
 416 **Table 2** Percentage changes and medians of three indicators. Absolute values which are higher
 417 than median represent that changes in these regions are more obvious, while the opposite means
 418 that changes in those regions are less significant.

| Region | Environmental inefficiency score | GDP | Emission intensity |
|---------------|----------------------------------|---------------|--------------------|
| Northeast | -4.20% | -2.60% | -0.96% |
| North | -2.04% | -2.21% | -0.77% |
| East coast | -7.78% | -1.13% | -2.02% |
| South coast | -42.25% | -4.90% | -3.00% |
| Central | -4.20% | -2.02% | -0.78% |
| Northwest | -5.08% | -1.21% | -1.36% |
| Southwest | -4.06% | -1.85% | -1.07% |
| Median | -4.20% | -2.02% | -1.07% |

419
 420 South coast region belongs to H-H pattern, whose percentage change of environmental
 421 inefficiency score and GDP values -42.25% and -4.90% respectively. Besides, percentage change
 422 of emission intensity is the highest, indicating raising tax rates would have the lowest emission per
 423 unit of total output in South coast region. It is because that industries in South coast region adjust
 424 their productive structures and relocate factories' sets due to the strict environmental regulation.
 425 Thus, the reduced emission affected by environmental policy poses positive effects on emission
 426 intensity. For example, in recent years, small sized enterprises are moved from Guangdong
 427 province to Hunan and Jiangxi province, which makes South coast region an outflow place of air
 428 pollution transfer ([Wu, 2016](#)). H-L pattern includes Northeast region and North region. They have
 429 high percentage changes of GDP, valued -2.60% and -2.21%, but low percentage changes of

430 environmental indicators. Economic development structures of Northeast region and North region
 431 depend mainly on heavy industry and conventional energy structure. Industrial productive
 432 activities are relied on an over-consumption of fossil fuel combustion (Wang & Zhao, 2017).
 433 However, the increase of emission charge makes enterprises reduce production intensity to reduce
 434 emission. Therefore, the low production intensity delays the speed of economic development.
 435 While L-H pattern contains Northwest region and East coast region, which rank the last two
 436 regions in percentage change of GDP. Regarding to East coast region, it has adequate financial
 437 support and advanced productive technology. Hence, the developed emission abatement technique
 438 can satisfy the abatement target instead of reducing production intensity to avoid emission.
 439 Moreover, L-L pattern includes Central region and Southwest region. In this pattern, all indicators'
 440 percentage changes are at low levels, indicating the weak effect of environmental policies on
 441 environmental protection and economic development. On one hand, raising emission charge
 442 would reduce the local emission and increase the environmental efficiency. On the other hand,
 443 raising environmental tax rates would lead to the reconstruction of the national industrial
 444 production layout, pollution would be transferred to Central region and Southwest region due to
 445 the emission leakage effect. Thus, local emission would increase and environmental efficiency
 446 would decrease. Therefore, the percentage changes of all indicators are not obvious because the
 447 positive effects neutralize the negative effects.

448

449
 450 **Figure 5.** The synergistic effects of different emission charge policies on carbon emission
 451 reduction. The hierarchical color shows the percentage change of carbon emission associated with
 452 total output when raising emission charge from pollutant discharge fees to environmental taxes.
 453 Rows mean regions, while columns represent industrial sectors (see Table S2).

1 454

2
3 455 From the above results we can see that, tightening emission charge policy would reduce
4
5 456 emission and reduce total output at the same time because of the trade-offs between environment
6
7 457 and economy. As we know, industrial productive processes are often accompanied by various
8
9 458 emissions, especially carbon emission. Thus, the reduction in total output due to the higher taxes
10
11 459 of environmental pollutions would also have synergistic effects on carbon emission reduction. For
12
13 460 purpose of discussing this effect of different sectors in different regions, we measure the
14
15 461 percentage change of carbon emission associated with total output under pollutant discharge fees
16
17 462 policy and environmental taxes policy (see Figure 5). In this study, we only consider the
18
19 463 synergistic effects of carbon emission reduction due to the total output reduction, other factors
20
21 464 such as abatement technical improvement or trade diversion are not included. Besides, we assume
22
23 465 that carbon emission factor is fixed under different emission charge policies. As reflected from
24
25 466 Figure 5, carbon emission in all regions decreases significantly in agriculture sector (code 01),
26
27 467 valued -11.18% in Northeast region, -6.37% in North region, -15.96% in East coast region, -44.06%
28
29 468 in South coast region, -9.96% in Central region, -11.72% in Northwest region, and -12.66% in
30
31 469 Southwest region, respectively. Additionally, compared with other regions, carbon emission
32
33 470 reduction in South coast region would be the most obvious, indicating that the emission charge
34
35 471 policy would have more obvious effects on both environment and economy in South coast region,
36
37 472 which, again, verifies the results in Section 4.2.
38
39
40

41 473

42 43 474 **4. Policy implications**

44
45
46 475 Some policy implications can be derived from the estimation of driving factors of
47
48 476 environmental productivity: 1) for technology dominant regions, further actions should aim at
49
50 477 increasing environmental efficiency. To do that, the local government should accelerate the
51
52 478 transfer of industrial development structure from high energy-intensive structure to low energy-
53
54 479 intensive structure by decreasing fossil fuels consumption and increasing clean energy
55
56 480 consumption. 2) For efficiency impeditive regions, they should develop industries that meet local
57
58 481 environmental requirements. More specific, reduction of iron production capacity, shutdown
59
60

1 482 coal-fired power plants, and replacement industrial boilers should be considered, which are
2 483 consistent with the conclusions in Qi et al. (2017) and Liu et al. (2018). 3) For co-driven regions,
3 484 they should promote pollution control technologies and experiences to assist other regions with
4 485 low level of environmental efficiency to progress.
5
6
7
8

9 486 Furthermore, some suggestions can be proposed from the analysis of economic and
10 487 environmental impacts of emission charge policy: 1) for H-H regions, raising environmental tax
11 488 rates are suggested since it could increase environmental efficiency obviously. Although GDP
12 489 declines pronouncedly because of the trade-offs between environment and economy, the decrease
13 490 of emission intensity indicates that environmental impact is greater than economic impact. 2) For
14 491 H-L regions, environmental policies are advised to adjusted based on the local development
15 492 targets. If the local strategy focuses on decreasing emission intensity and puts less emphasis on
16 493 increasing GDP, then raising environmental tax rates is suggested. Otherwise, if economic
17 494 development is the main target, then maintaining the current tax rates is the best choice. 3) For
18 495 L-H regions, it is recommended to raise environmental tax rates because a higher tax rate would
19 496 lead to a higher progression of environmental productivity and a lower regression of GDP. 4) For
20 497 L-L regions, holding the current tax rates is advised if there is no need to reduce emission intensity
21 498 immediately because both environmental impacts and economic impacts of raising environmental
22 499 tax rates are tiny.
23
24
25
26
27

37
38
39
40

41 500

42 501 **5. Conclusion**

43
44 502 From 2007 to 2012, all regions experience environmental productivity progresses. Southwest
45 503 region ranks the top in GLPI (valued 0.2101) because of the excellent resource endowment and
46 504 environmental conditions. While North region is the least progressive region, valued 0.086 in
47 505 GLPI, due to the conventional economic structure with high energy consumption and high
48 506 emission. Furthermore, according to the driving factors of environmental productivity, seven
49 507 regions can be divided into three modes. Northeast region, North region, East coast region, Central
50 508 region and Northwest region belong to technology dominant mode. Technical improve greatly in
51 509 these regions because local development strategies encourage them to renovate technology and
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 510 eliminate backward productive technique. Southwest region belongs to efficiency impeditive
2 511 mode, indicating that technical efficiency poses a negative effect on environmental productivity
3
4 512 progress. Industrial development actions like construction of high emission industrial bases in
5
6 513 these regions lead to the regress of technical efficiency. South coast region belongs to co-driven
7
8 514 mode. In this mode, technical efficiency change and technology change have similar contributions
9
10 515 to environmental productivity progress due to the superior geographical position and abundant
11
12 516 capital support for technical innovation and economic structure improvement.
13
14

15 517 Additionally, according to the effect evaluation of emission charge policies on economy and
16
17 518 environment, seven regions can be characterized into four patterns. H-H pattern covers South
18
19 519 coast region, indicating both economic impact and environmental impact are at high levels. H-L
20
21 520 pattern includes Northeast region and North region, representing the environmental impact is low
22
23 521 but the economic impact is high. L-H pattern includes Northwest region and East coast region,
24
25 522 which has the opposite meaning with H-L pattern. While, L-L pattern contains Central region and
26
27 523 Southwest region, which has the opposite meaning with H-H pattern. Although the degree to
28
29 524 which effects of emission charge policies on environment and economy are different in the
30
31 525 specific region, the complex effect is positive since the percentage changes of emission intensity
32
33 526 in all regions are decline when tightening the emission charge policy.
34
35

36
37 527 Nevertheless, there are several limitations of this study. In order to reflect the material flow
38
39 528 among various industrial sectors and figure out the impacts of environmental policy on economic
40
41 529 production, input-output tables are chosen to be the basic economic dataset. The last two issues of
42
43 530 provincial input-output tables of 30 Chinese provinces are in 2007 and 2012, thus, we choose
44
45 531 these two years for the analysis. Considering the rapid economic development and changes in
46
47 532 production structure, the illustrations would be more accurate using the more recent values if the
48
49 533 data is available. Additionally, data related with emission abatement at sector level is incomplete.
50
51 534 Thus, we have to assess some environmental variables of each sector based on hypothesis, leading
52
53 535 to inaccuracy. Furthermore, material flow of different regions would lead to emission leakage
54
55 536 embodied in trade. Future study can be conducted with the consideration of the material flow and
56
57 537 emission leakage among multi-regions to figure out the effects of emission charge policy on
58
59 538 multi-regional emission leakage and analyze the regional unfairness of emission charge policy.

| 14 | P | 48 | As | 56 |
| 15 | PP | 49 | Cu | 57 |
| 16 | | | | |
| 17 | VP | 50 | Zn | 58 |

663

664 **Table S3** Taxable pollutions and the corresponding equivalent units

| Pollution | Equivalent unit (equivalent/kg) |
|------------------------------------|---------------------------------|
| Air pollution | |
| Sulfure dioxide (SO ₂) | 0.95 |
| Nitrogen oxides (NO _x) | 0.95 |
| Soot and dust (SD) | 3.09 |
| Water pollution | |
| Chemical oxygen demand (COD) | 1 |
| Ammonia nitrogen (AN) | 0.8 |
| Phosphorus (P) | 0.25 |
| Petroleum pollutants (PP) | 0.1 |
| Volatile phenol (VP) | 0.08 |
| Cyanide (Cy) | 0.05 |
| Aquatic Hg (Hg) | 0.0005 |
| Aquatic Cd (Cd) | 0.005 |
| Aquatic Cr (Cr) | 0.04 |
| Aquatic Pb (Pb) | 0.025 |
| Aquatic As (As) | 0.02 |
| Aquatic Cu (Cu) | 0.1 |
| Aquatic Zn (Zn) | 0.2 |
